### 1. INTRODUCTION

Planet formation may start during the embedded phase of star formation. In the scenario where planets form from the embedded disks, resulting in substructures, the chemistry of embedded disks may play a significant role for the chemical composition of the forming planets. In the recent years, observations discover the emission of carbon-chain molecules and complex organic molecules (COMs) toward the center of several embedded protostars, indicating that embedded protostars have developed a complex chemistry at the disk-forming region. If the forming planets inherit the chemistry of embedded disks, the abundance of complex organic molecules may implicate future developments of organics on the planets.

Heavier or more complex molecules, such as cyclic- $C_3H_2$ , SO, and complex organic molecules (COMs), are in the gas phase at the inner protostellar envelope ( $T \gtrsim 100 \,\mathrm{K}$ ), exclusively tracing the properties of the inner envelope where a disk may be forming (Aikawa 2013; Sakai et al. 2014). The kinematics of a rotating infalling envelope has been analyzed with the observations of heavier or more complex molecules, such as CH<sub>3</sub>OH and CH<sub>2</sub>DOH for HH 212 (Lee et al. 2017), CS for IRAS 04365+2535 (Sakai et al. 2016) and L483 (Oya et al. 2017), cyclic-C<sub>3</sub>H<sub>2</sub> for L1527 (Sakai et al. 2014), OCS for IRAS 16293-2422 A (Oya et al. 2016), and methanol and HCOOH for B335 (Imai et al. 2019).

In the review by Herbst & van Dishoeck (2009), complex molecules are defined as carbon-bearing molecules that contain six atoms or more. Saturated complex molecules are rich in hydrogen atoms, often called complex organic molecules (COMs), while the unsaturated complex molecules are lack of hydrogen atoms, mostly in the form of long carbon-chain molecules. While recent observations show several embedded protostars with rich spectra of complex molecules, the occurrence of complex molecules at embedded protostars and its relation-

Corresponding author: Yao-Lun Yang yaolunyang.astro@gmail.com

ship to the star formation process remain poorly understand. Several protostars are rich in COMs but show little emission of long carbon-chain molecules, such as IRAS 16293–2422 (Jørgensen et al. 2016), NGC 1333 IRAS 4A (Bottinelli et al. 2004), B335 (Imai et al. 2016, 2019), and BHR 71 (Yang et al. 2020 accepted); some protostars are rich in long carbon-chain molecules but not in COMs, such as L1527 (Sakai et al. 2010) and IRAS 15398–3359 (Sakai et al. 2009). While the bimodal chemical appearance hints a bimodal evolutionary path, the chemical evolution at the embedded protostars remain ill-constrained as a few protostars show the emission of both COMs and long carbon-chain molecules at different scales, such as L483 (Oya et al. 2017).

The Perseus ALMA Chemistry Survey (PEACHES) aims to provide the statistics on the occurrence of complex molecules at embedded protostars. This program unbiasedly observes 51 embedded protostars with ALMA around 260 GHz, covering the emission of simple molecules such as CS and H<sup>13</sup>CN as well as the emission of complex molecules including CH<sub>3</sub>OH and CH<sub>3</sub>OCHO.

### 2. OBSERVATIONS

### 3. RESULTS

The ALMA image cubes are post-processed to extract 1D spectra for identifying the emission of complex molecules and more in-depth analyses. Because the complex molecules only sublime at the temperature greater than  $\sim\!100\,\mathrm{K}$ , we focus on the spectra toward the continuum sources. Four steps of post-processing reduces the image cubes to 1D spectra, which are summarized below.

• Continuum fitting: We use the CASA task imfit to iteratively fit for continuum sources down to  $5\sigma$  of the residual image within the central 70% of the primary beam size (20"). For Set3-ID09, the fitting uses a threshold of  $4\sigma$  and extends the mask to the entire primary beam as a continuum source is detected toward the edge of the primary beam where the noise is elevated.

• Extracting spectra: We use the CASA task specflux to extract the mean flux density within the ellipse which has the same major and minor axes as well as the position angle as the fitted continuum sources.

- Baseline calibration: The continuum has been removed before the imaging process; however, the extracted spectra sometimes still show imperfect baselines. The spectra show significant differences from one to another such as rich emission lines, lack of emission, and broad emission features. Thus, we manually select the frequency ranges for baseline calibration for each spectral window and each field.
- Velocity correction: Finally, the frequency of the extracted spectra are corrected according to the source velocities. We collect the source velocities from the literature as well as from the strong emission lines in our spectra. Table 1 lists the adopted source velocities and the corresponding references.

Figure 1 shows the images of the continuum along with the fitted shapes, while the properties of the continuum sources are listed in Table 1. Our observations detect 50 continuum sources. The continuum emission appears as compact circular or elliptical shape with no sub-structure. Some sources show extended continuum emission resembling the shape of outflow cavities.

Three sources, EDJ2009-237, Per-emb-60, and EDJ2009-172, have no spectral line detected; therefore, we exclude them from spectral extraction as well as the line identification and modeling. These three sources still need to be included for detection number statistics.

### 3.1. Line Identifications and Modeling

Line identification starts with manual identification and verification for a few sources with rich spectra, including Per-emb-12B and B1-bS. We use SPLATALOGUE<sup>1</sup> to identity the molecular species and use XCLASS (Möller et al. 2017) to verify the identification. The XCLASS package is a LTE radiative transfer code that uses the molecular data from the Cologne Database of Molecular Spectroscopy (CDMS; Müller et al. 2001, 2005; Endres et al. 2016) and the Jet Propulsion Laboratory (JPL; Pickett et al. 1998). An identification needs to satisfy the following criteria.

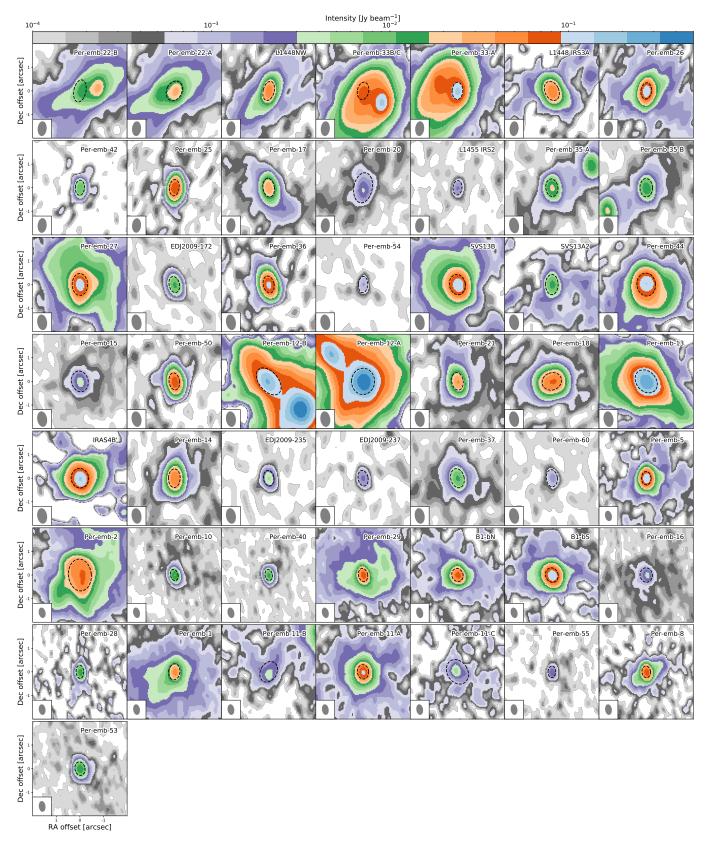

• The spectra agree with the predicted strengths of the model.

- The spectral lines are not all blended with other emission, such as other molecules and the SiO emission tracing the outflows. The emission of a few species, such as HDCO & <sup>13</sup>CH<sub>3</sub>OH, CH<sub>3</sub>CHO & CH<sub>2</sub>DOH, <sup>34</sup>SO & C<sub>2</sub>H<sub>5</sub>OH, and CH<sub>3</sub>OCH<sub>3</sub> & CH<sub>2</sub>DCN, are partially blended (blending occurs at a few lines but other lines remain isolated). The fittings of those species are performed together to verify their identification.
- Identified molecules need to be already found toward young stellar objects as summarized in McGuire (2018).

Table 3 lists the identified species and transitions. Only identifiable transitions are listed. The XCLASS modeling includes all the transitions in our frequency coverage regardless their Einstein-A values and upper energy levels.

Systematic spectral fitting using XCLASS is then applied to all sources using a list of species, compiled from those identifications. The catalogs used in this study are listed in Appendix A The fitting function in XCLASS includes several optimization algorithms that can be used in series to reduce biases. We configure the algorithm chain that starts with the genetic algorithm followed by the Levenberg-Marquardt  $\chi^2$  minimization. The genetic algorithm searches the best-fitting parameters iteratively with generations that evolve like a natural selection, where the better fitting models get less modification over generations. We setup the genetic algorithm to search for the top two best-fitting models after 30 generations. Then, the Levenberg-Marquardt  $\chi^2$  minimization applies to the three best-fitting models for 20 iterations to find the best-fitting models. The genetic algorithm aims to find possible local minimums and the Levenberg-Marquardt minimization further find the best-fitting models in the local minimums. The two best-fitting models found by the genetic algorithm often very similar, suggesting that there is only one minimum. To address the rare cases of two local minimums, we pick the model with the lower  $\chi^2$  values from the two bestfitting models constrained by the Levenberg-Marquardt minimization. We assume the COMs are all concentrated at the center, simplified as a 2D thin circular disk. There are four parameters for the XCLASS modeling, the size of the emitting molecule  $(r_{\text{COM}})$ , the excitation temperature  $(T_{\rm ex})$ , the column density  $(N_{\rm COM})$ , and the line width  $(\Delta \nu)$ . Due to the limited frequency coverage, many species only have a few lines detected, we fix  $r_{\text{COM}}$  as 0.75, similar to our beam size, and optimize the model with five excitation temperatures, 100, 150, 200, 250, and 300 K. We allow the line width varying between  $1.2\,\mathrm{km\,s^{-1}}$  to  $3.5\,\mathrm{km\,s^{-1}}$  for better fitting

http://www.splatalogue.net/

**Figure 1.** The continuum images of all PEACHES protostars. Non-detections toward L1448 IRS 2E and NGC 1333 SVS 3 are not shown. The dashed ellipses illustrate the size of fitted continuum, which is the region for extracting 1D spectra.

quality, and the range of the column density for each molecule is chosen according to the strength of the emission. The range of fitted column densities at different

temperatures indicates the uncertainty of the column densities.

The uncertainty from the fitting.

 $<sup>^</sup>a\mathrm{The}$  typical quantum numbers are listed as  $[J,\,K_\mathrm{a},\,K_\mathrm{c}]$  unless specified.

## 4. CONTINUUM OPACITY

### 5. DETECTION STATISTICS

We summarize the fraction of sources with detections of molecules in Figure 2. The detection statistics include COMs, carbon-chain molecules, and the simple organic molecules, such as CS, H<sup>13</sup>CN, SO, <sup>34</sup>SO, and SO<sub>2</sub>. The PEACHES protostars show a great chemical diversity from no molecule detected (B1-bN) to rich spectra of COMs (e.g. Per-emb-12B). Detections of COMs and the number of COMs detected show no obvious correlation

with the bolometric luminosity and bolometric temperature of the protostars, which are conventional evolutionary indicators. Low luminosity sources have fewer COMs detected; however, if COMs mostly come from thermally desorption, the region with  $T>T_{\rm desorption}$  may be smaller for the low luminosity sources, making the emission of COMs fainter and reducing our sensitivity to detect COMs. We also compare the detection statistics with the mass derived from 9 mm observations that resolved the sources as a proxy of the central mass (Tychoniec et al. 2018). The detection statistics show no clear correlation with the central mass; however, the

<sup>&</sup>lt;sup>b</sup> The quantum numbers are [N, J, F]

sources with smaller central mass have fewer detections of COMs, which may due to their low luminosity.

#### 6. EXCITATION TEMPERATURES

6.1.  $CH_3OH$ 

6.2.  $CH_3 OCHO$ 

#### 7. THE SPECTRA OF CCH

Due to the absorption and irregular line profile, the XCLASS fitting routine often fails to faithfully reproduce the observed CCH spectra.

#### 8. CORRELATIONS OF COMS

The chemical evolution of protostars may leave certain patterns in the abundance of molecules as the dynamical evolution determines the density and temperature structures, regulating chemical reactions. Thus, the abundance of COMs and their correlations provide critical information to constrain the chemical evolution at embedded protostars. The fitted column density of COMs indicates the abundance of COMs around protostars. Typically COMs are locked into the ices on dust grains at outer envelope. Therefore, we take the column density of COMs as a proxy of the abundance of COMs.

As described in Section 3.1, we fit the column density and line width with different excitation temperatures, resulting in a range of column density as its uncertainty. The comparison between CCH and CH<sub>3</sub>OH shows no correlation between these two molecules (Figure 3), similar to the conclusion in Higuchi et al. (2018). The single dish survey by Graninger et al. (2016) shows a correlation between C<sub>4</sub>H, a more complex carbon-chain molecules, and CH<sub>3</sub>OH. Outflow activity can promote the formation of CCH, which is more efficiency at warm temperature. In face, the morphology of CCH often traces the outflow cavities seen from CS. Therefore, the lack of correlation between CCH and CH<sub>3</sub>OH may be affected by outflows.

Figure 5 shows the correlations of several COMs selected from their detection rates. The column density of  $\mathrm{CH_3OH}$  best correlates with that of  $\mathrm{CH_3CN}$ . Belloche et al. (2020) also found the tight correlation between these two molecules. The column densities of  $\mathrm{CH_3OCH_3}$  and  $\mathrm{CH_3OCHO}$  also show a tight correlation. To quantify the goodness of correlation, we calculate the Pearson's correlation coefficient (r), which tests the linearity of two variables. A simple calculation of the Pearson's correlation coefficient would ignore the uncertainties of the column density as well as the upper limits. Thus, we use the bootstrapping method to sample the fitted column densities and upper limits to calculate Pearson's r. For detections, we assume a normal distribution centers on the best-fitted values with the uncer-

tainty as the width of the normal distribution; for non-detections, we assume a normal distribution centers at zero with a width of one third of the upper limit, which is the  $3\sigma$  upper limit. Figure 4 shows the distributions of the Pearson's r for the correlation between CH<sub>3</sub>OH and CH<sub>3</sub>OCHO after 10000 resampling for all derived column densities (detections & non-detections) and the detection-only sample. With the detection-only sample, the mean Pearson's  $r_d$  is 0.92, as expected for a tight correlation, with a Gaussian-like distribution skewed toward lower values. After including the upper limits, the mean Pearson's r decreases to 0.65 with larger uncertainty (the 95% credible interval increases by 76%). If we take  $r \geq 0.5$  and  $r_d \geq 0.9$  as the criteria for having correlations, (to be updated after updating the figure).

### 9. SPATIAL EXTENT OF COMS

### 10. DISCUSSION

10.1. Notes on the 1D Spectra

L1448 IRS 3A-

• The emission of SO and CS shows additional redshifted component, separated by  $\sim 4.6 \,\mathrm{km}\,\mathrm{s}^{-1}$ .

Per-emb-33-A—

- Strong absorption at 246509 MHz.
- HDCO seems to have two components for the transition at 246925 MHz, but the one at 259035 MHz only has one component, which is underestimated by the model.

Per-emb-33-B/C-

• CCH shows three components leading to an inaccurate fit.

Per-emb-42-

- Double-peaked CS line
- Triple-peaked CCH line

Per-emb-26—

- Red-shifted excess appears in the CS, SO, CH<sub>3</sub>OH, H<sup>13</sup>CN, and HDCO lines.
- Broad SO lines peak at slightly blue-shifted velocity ( $\sim 1 \,\mathrm{km}\,\mathrm{s}^{-1}$ ).
- The best-fitting model overestimates the CH<sub>3</sub>CH<sub>2</sub>CN, CH<sub>3</sub>CHO, and c-C<sub>3</sub>H<sub>2</sub> lines, possibly due to the contamination of SiO, which should have been excluded for fitting. Tests are running now.
- The secondary CH<sub>3</sub>OH line becomes overestimated at  $T_{\rm ex} \ge 200$  K.
- Unidentified lines at 246525 MHz and 244249 MHz.

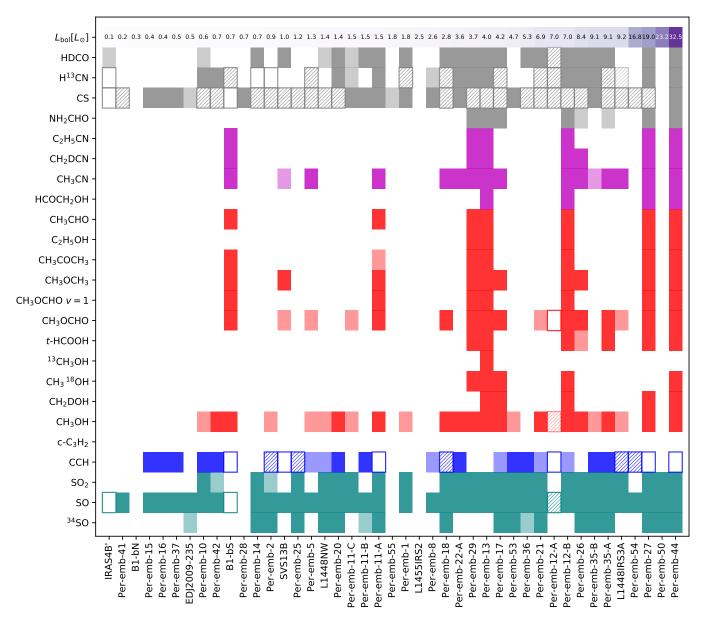

Figure 2. The detection statistics sorted by their bolometric luminosity.

## Per-emb-22-B-

- The SO lines have small red-shifted excess. The best-fitting line strength decreases significantly at  $T_{\rm ex}$  =200 K. Not sure why.
- The SO line profiles are slightly skewed toward blue-shifted velocity, while the CS line shows another brighter peak at blue-shifted velocity.

# Per-emb-22-A —

 $\bullet$  Hints of CH<sub>3</sub>OCHOemission, but not significant enough to warrant a detection.

Per-emb-17—

- Many line profiles exhibit a broad double-peaked profile, separated by  $\sim 5-6\,\mathrm{km\,s^{-1}}$ . Per-emb-17 is a binary system unresolved by our observations. However, the channel maps suggest that the two components are likely to surrounding the southern source, Per-emb-17-B.
- The CH<sub>3</sub>OCHO line at  $\sim$ 259343 MHz may be optically thick.

## Per-emb-20—

 The CCH lines have a narrow double-peaked profile. The CS line shows a similar double-peak profile.

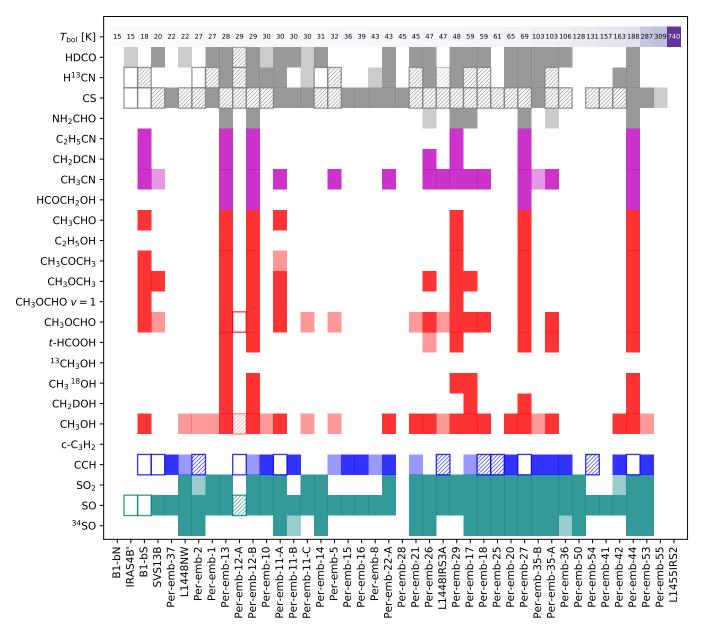

Figure 2 (Cont.). The same figure as Figure 2 but sorted by their bolometric temperature.

• The SO lines have a broad component underneath the typical narrow lines.

#### SVS13 A2-

- Weak indication of the unidentified line at 246525 MHz, which has been detected in other sources.
- The model strength of CCH suddenly decreases at  $T_{\rm ex}$  =200 K by  $\sim$ 0.5 K over a 2 K line.

## Per-emb-44—

 Unidentified lines at 244248 MHz, 246219 MHz, 246254 MHz, 246344 MHz, 246389 MHz, 246434 MHz,

- $246525\,\mathrm{MHz},\,246838\,\mathrm{MHz},\,258268\,\mathrm{MHz},\,258271\,\mathrm{MHz},$  and  $262068\text{-}262070\,\mathrm{MHz}.$
- Higher temperatures (Tex > 100 K) provide better fittings. Probably should adopt the temperature fitted from CH<sub>3</sub>OCHO (previous MCMC fitting suggests a temperature of 263 K).

#### Per-emb-12-B-

 $\bullet$  Unidentified lines at 244248 MHz, 246254 MHz, 246314 MHz, 246322 MHz, 246389 MHz, 246434 MHz, 246525 MHz, 246696 MHz, 246838 MHz, 246873 MHz, 247082 MHz, 258268 MHz, 258271 MHz, and 262068-262070 MHz.

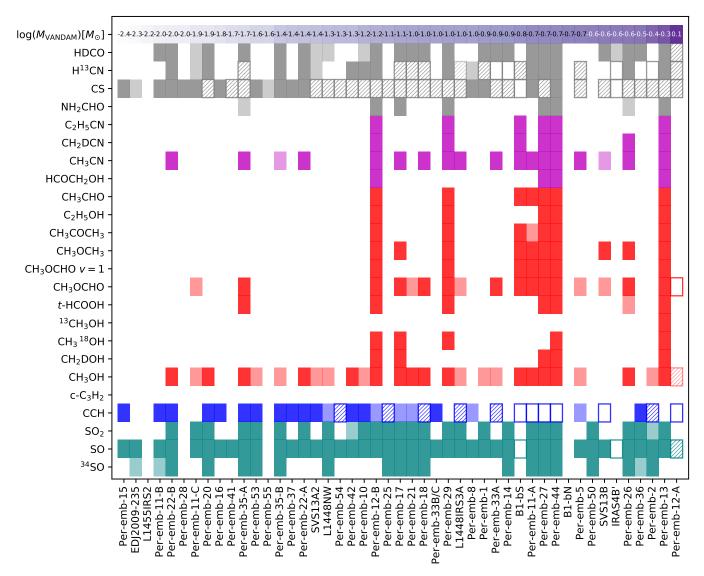

Figure 2 (Cont.). The same figure as Figure 2 but sorted by their mass derived from their 9 mm observations (Tychoniec et al. 2018).

### Per-emb-12-A —

• Strong absorption features detected across the spectra, CCH, SO, H<sup>13</sup>CN, CS, CH<sub>3</sub>OH, HDCO, CH<sub>3</sub>CN, and CH<sub>3</sub>OCHO.

### IRAS4B1—

• Spectra show no emission along with absorption at SO, CS, and CH<sub>3</sub>OH lines.

### Per-emb-13—

- The CH<sub>3</sub>OCHO emission needs  $T_{\rm ex} > 100$  K to have a good fit.
- All three CH<sub>3</sub>OH lines are detected but two of them show clear sign of self-absorption, therefore, not ideal for fitting the excitation temperature.

- Unidentified lines at 244248 MHz, 246254 MHz, 246331 MHz, 246344 MHz, 246434 MHz, 246525 MHz, 246838 MHz, 246974 MHz, 247086 MHz, 257268 MHz, 257271 MHz, 259323 MHz, 259331 MHz, 262098 MHz, and 262109 MHz.
- The best-fitting models have two different widths for the CH<sub>3</sub>CHO lines.
- The best-fitting model for <sup>13</sup>CH<sub>3</sub>OH lines overestimates the line width.

#### Per-emb-27—

All three CH<sub>3</sub>OH lines are detected, but none
of the temperature produce a good fit to all
three lines, suggesting that some lines are optically thick. The transitions at 243916 MHz and

Figure 3. Correlation of the column densities of CCH and  $\mathrm{CH_3OH}$  fitted from the PEACHES protostars. The sources where both molecules are detected are shown in black; the sources where only one molecule is detected are shown in magenta; finally, the sources where both molecules are not detected are shown in black for the corresponding upper limits.

**Figure 4.** Distributions of Pearson's correlation coefficient from 10000 resamples drawn from detections + non-detections and only detections. The legend indicates the mean values of Pearson's r along with the range of the 95% credible interval as the associated uncertainties.

 $261806\,\mathrm{MHz}$  are  ${\sim}30$  K, while the transition at  $246873\,\mathrm{MHz}$  is about 24 K. They seems to be optically thick. In comparison, the continuum brightness temperature is only 5.8 K.

 $\bullet$  Unidentified lines at  $244232\,\mathrm{MHz},\ 244248\,\mathrm{MHz},\ 246207\,\mathrm{MHz},\ 246254\,\mathrm{MHz},\ 246388\,\mathrm{MHz},\ 246435\,\mathrm{MHz},\ 246525\,\mathrm{MHz},\ 246538\,\mathrm{MHz},\ 246838\,\mathrm{MHz},\ 246973\,\mathrm{MHz},\ 247084\,\mathrm{MHz},\ \mathrm{and}\ 259330\,\mathrm{MHz}.$ 

• The CH<sub>3</sub>OH line at 243916 MHz and the SO lines become optically thick at 100 K.

#### Per-emb-54—

- The SO lines appears red-shifted by  $\sim 2 \,\mathrm{km \, s^{-1}}$ .
- The emission of CS and CCH shows a blue-shifted peak along with absorption slightly red-shifted compared to the source velocity.

#### Per-emb-21—

• Emission of CH<sub>3</sub>OH is detected. However, the broad widht and noisy spectra lead to a bad fit. The best-fitting model has the maximum line width allowed,  $3.5\,\mathrm{km\,s^{-1}}$ .

### Per-emb-14—

• The best-fitting model underestimates the HDCO lines, possibly due to the simultaneously fitted <sup>13</sup>CH<sub>3</sub>OH lines.

#### Per-emb-35-B—

- The best-fitting model underestimates the SO lines at  $T_{\rm ex} = 100$  K.
- The CCH lines show a double-peaked line profile.
- The CH<sub>3</sub>OH line at 243915 MHzhas an S/N of 1.2, but hints the existence of CH<sub>3</sub>OH.

#### Per-emb-35-A —

- The goodness of fitting for the  $CH_3OH$  lines is a strong function of temperature, suggesting that the  $CH_3OH$  lines can indicate the  $T_{ex}$ .
- The CH<sub>3</sub>OCHO line at 259342 MHz has an S/N of 1.8, but hint the existence of CH<sub>3</sub>OCHO.

#### SVS13B—

• The fitted width of the HDCO lines is overestimated.

### Per-emb-15—

All lines have only the blue-shifted emission, making them blue-asymmetric.

### Per-emb-50—

• The SO and SO<sub>2</sub> lines have a very broad component  $(\Delta \nu = 6 \,\mathrm{km}\,\mathrm{s}^{-1})$ , skewing toward the blue-shifted velocity.

Figure 5. Corner plot of the correlations of the column densities between CH<sub>3</sub>OH, CH<sub>3</sub>CN, CH<sub>3</sub>OCHO, CH<sub>3</sub>OCH<sub>3</sub>, CH<sub>3</sub>CHO, CH<sub>3</sub>CH<sub>2</sub>CN, and t-HCOOH. The color code follows that in Figure 3. The dashed line indicates equality. The legends incidcate the Pearson's r for the detection-only sample  $(r_d)$  and the entire sample (r) along with the ranges of 95% credible interval.

Per-emb-18—

- Many transitions of  ${\rm CH_3OCHO}$  are tentatively detected; however, none of them has  ${\rm S/N} > 3$ . Currently categorized as non-detection.
- $\bullet$  The HDCO lines are broader than the maximum allowed line width,  $3.5\,\rm km\,s^{-1},$  making the fitting inaccurate.

Per-emb-37—

• The fitting of SO lines has a strong variation as a function of temperatures.

Per-emb-36—

• The SO lines are underestimated by the bestfitting model. Perhaps it can be fixed by changing

the Variation parameter. To be tested. Test run on laptop shows no issue of having a good fit at 100 K for SO with Variatopn  $= 10^{-2}$ .

The CCH lines only show at the blue-shifted velocities.

### B1-bS—

- Higher temperatures produce worse fittings to the CH<sub>3</sub>OCHO lines. Previous MCMC fitting of the CH<sub>3</sub>OCHO lines suggests a temperature of 58 K.
- The fitting of  $CH_3OCH_3$  is limited by the minimum line width of  $1.2 \,\mathrm{km}\,\mathrm{s}^{-1}$ .
- Unidentified lines at 246027 MHz, 246099 MHz, 246143 MHz, 246192 MHz, 246525 MHz, 246674 MHz, and 2467320 MHz.
- The CH<sub>3</sub>OCHO lines around 258278 MHz and the H<sup>13</sup>CN lines have a few dips within the line profile, suggesting absorption or just noisy spectra.

#### Per-emb-29—

• Only two CH<sub>3</sub>OH lines are covered. Both lines have a strength of  $\sim 10$  K, suggesting optically thick.

#### Per-emb-5—

• The CCH fitting is not robust across different temperatures (only 150 K and 300 K fit).
